Reproductive Techniques

Policy Number: 4.02.04  Last Review: 12/2017
Origination: 10/1988  Next Review: 12/2018

Policy
Blue Cross and Blue Shield of Kansas City (Blue KC) will provide coverage for assisted reproductive technology (ART) when it is determined to be medically necessary because the criteria shown below are met.

When Policy Topic is covered
Coverage of infertility treatment using assisted reproductive technology is a contract-specific benefit issue. Where benefits are available, all of the services identified by the CPT codes listed below might be considered eligible benefits unless indicated as being investigational.

Some contracts that cover ART treatment may have different member co-pay formulas and limits on these services than for other medical-surgical coverage.

The following reproductive techniques are considered medically necessary;
- cryopreservation of testicular tissue in adults with azoospermia as part of an intracytoplasmic sperm injection procedure;
- intracytoplasmic sperm injection for infertility;
- blastocyst transfer

The following lists summarize the CPT codes used to describe ART. Those procedures performed in order to diagnose infertility, i.e. laparoscopy and semen analysis, are not included in this review. Not all steps are routinely done in each case.

Procedures performed on the patient

<td>Assisted embryo hatching, any method. Assisted hatching is a technique performed to enhance the likelihood that the transferred embryo will implant in the uterus and establish a viable pregnancy. The technique involves in vitro disruption of the zona pellucida surrounding the embryo so that the embryo can “escape” and implant into the uterine wall. Assisted hatching has also been referred to as zona drilling and partial zonal dissolution. Assisted hatching is commonly performed as part of an IVF procedure in women over 40 who have a decreased incidence of implantation after embryo transfer and in women with prior failed IVF cycles due to failed implantation.</td>

When Policy Topic is not covered
The following laboratory procedures are considered investigational:

- assisted hatching;
- co-culture of embryos;
- cryopreservation of ovarian tissue, or oocytes; cryopreservation of testicular tissue in prepubertal patients; storage and thawing of ovarian tissue, oocytes or testicular tissue
- intracytoplasmic sperm injection in the absence of infertility.
Co-culture techniques involve tissue culture of human embryos in the presence of oviductal, uterine, granulosa, or other cells. The procedure involves the isolation of the substrate cells, culture, plating, and co-culture of these cells with human embryos. The purpose of co-culture is to produce a more viable embryo at the blastocyst stage of development for subsequent transfer to the uterus. Co-culture is not routinely done as part of all IVF procedures; the technique may not be available in all infertility labs.

The policy addresses a variety of techniques available to establish a viable pregnancy for couples who have been diagnosed with infertility and for whom assisted insemination was unsuccessful.

For individuals who have infertility who receive in vitro fertilization (IVF) with assisted hatching, the evidence includes randomized controlled trials (RCTs), a systematic review, and a large observational study. Relevant outcomes are health status measures, resource utilization, and treatment-related morbidity. RCTs have not shown that assisted hatching improves the live birth rate compared with standard care. Findings on clinical pregnancy rate after assisted hatching were mixed but RCTs generally did not find improvement with assisted hatching versus standard care. A large observational study found that assisted hatching was associated with worse outcomes. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have infertility who receive IVF with embryo co-culture, the evidence includes RCTs and case series. Relevant outcomes are health status measures, resource utilization, and treatment-related morbidity. Most clinical trials did not find improved implantation or pregnancy rate after co-culture, and studies have not reported the live birth rate. Moreover, co-culture techniques have not been standardized and 1 RCT that found a higher clinical pregnancy rate with co-culture than a standard practice control group used a novel technique that has not been otherwise evaluated. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have cancer who will undergo treatment that may lead to infertility who receive cryopreservation of ovarian tissue, the evidence includes case series. Relevant outcomes are health status measures, resource utilization, and treatment-related morbidity. The technique has not been standardized and there is a lack of controlled studies on health outcomes following cryopreservation of ovarian tissue. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have cancer who will undergo treatment that may lead to infertility who receive cryopreservation of oocytes, the evidence includes RCTs and a systematic review on the technique in related populations. Relevant outcomes are health status measures, resource utilization, and treatment-related morbidity.
The systematic review found that fertilization rates ranged from 71% to 79%, and the clinical pregnancy rates per transfer ranged from 36% to 61%. The available studies are conducted in highly selected populations and may not be generalizable to the population of interest, women with cancer. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have infertility who receive IVF with blastocyst transfer, the evidence includes RCTs and meta-analyses. Relevant outcomes are health status measures, resource utilization, and treatment-related morbidity. RCTs and meta-analyses have found that blastocyst transfer is associated with higher live birth rates compared with cleavage stage transfer. One meta-analysis found a significantly higher rate of preterm birth after blastocyst stage versus cleavage stage transfer, but not find increased risks of other outcomes such as low birth rate and perinatal mortality. The evidence is sufficient to determine qualitatively that the technology results in a meaningful improvement in the net health outcome.

For individuals who have male factor infertility who receive IVF with intracytoplasmic sperm injection (ICSI), the evidence includes observational studies and a systematic review. Relevant outcomes are health status measures, resource utilization, and treatment-related morbidity. No RCTs are available. Observational studies, which are subject to limitations (eg, selection bias), have found similar rates of clinical pregnancy and live birth after ICSI and standard IVF, and a meta-analysis of observational studies found a higher rate of genitourinary malformations in children born after ICSI but only when lower quality studies were included in the analysis. RCTs comparing health outcomes after ICSI for male factor infertility and standard IVF are needed. The evidence is insufficient to determine the effects of the technology on health outcomes.

Clinical input was obtained in 2012, and there was general agreement among reviewers that ICSI in men with male infertility factor was considered medically necessary.

For individuals who have azoospermia who receive cryopreservation of testicular tissue as part of ICSI, the evidence includes no clinical trials. Relevant outcomes are health status measures, resource utilization, and treatment-related morbidity. Cryopreservation of testicular tissue in adult men with azoospermia is a well-established component of the ICSI procedure. However, there is a lack of clinical trials. The evidence is insufficient to determine the effects of the technology on health outcomes.

Clinical input was obtained in 2012 and there was general agreement among reviewers that cryopreservation of testicular tissue in adult men with azoospermia was considered medically necessary.

For individuals who are prepubertal boys with cancer who receive cryopreservation of testicular tissue, the evidence includes no clinical trials. Relevant outcomes are health status measures, resource utilization, and treatment-related morbidity. No
clinical trials were identified evaluating the safety and efficacy of cryopreservation of testicular tissue in prepubertal boys undergoing cancer therapy. The evidence is insufficient to determine the effects of the technology on health outcomes.

**Background**
Infertility can be due either to female factors (i.e., pelvic adhesions, ovarian dysfunction, endometriosis, prior tubal ligation), male factors (i.e., abnormalities in sperm production, function, or transport or prior vasectomy), a combination of both male and female factors, or unknown causes. Various reproductive techniques are available to establish a viable pregnancy; different techniques are used depending on the reason for infertility.

Assisted reproductive technologies (ART), as defined by the Centers for Disease Control (CDC) and other organizations, refers to fertility treatments in which both the eggs and sperm are handled. Not included in ART is assisted insemination (artificial insemination) using sperm from either a woman’s partner or a sperm donor. In most instances ART will involve in vitro fertilization (IVF), a procedure in which oocytes harvested from the female are inseminated in vitro with sperm harvested from the male. Following the fertilization procedure, the zygote is cultured and ultimately transferred back into the female’s uterus or fallopian tubes. In some instances, the oocyte and sperm are collected, but no in vitro fertilization takes place, and the gametes are reintroduced into the fallopian tubes. Examples of ART include, but are not limited to, gamete intrafallopian transfer (GIFT), transuterine fallopian transfer (TUFT), natural oocyte retrieval with intravaginal fertilization (NORIF), pronuclear state tubal transfer (PROST), tubal embryo transfer (TET), zygote intrafallopian transfer (ZIFT), gamete and embryo cryopreservation, oocyte and embryo donation, and gestational surrogacy.

The various components of ART and implantation into the uterus can be broadly subdivided into oocyte harvesting procedures, which are performed on the female partner; sperm collection procedures, which are performed on the male partner; and the in vitro component, i.e., the laboratory procedures, which are performed on the collected oocyte and sperm. The final step is the implantation procedure.

The majority of CPT codes describing the various steps in ART procedures are longstanding techniques. This includes codes for oocyte retrieval, sperm isolation, culture and fertilization of the oocyte, and embryo; zygote; or gamete transfer into the uterus or fallopian tubes. Only the relatively new reproductive techniques (i.e., intracytoplasmic sperm injection, assisted hatching, co-culture of embryos) and cryopreservation of reproductive tissue (i.e., testicular, ovarian, or oocytes) will be considered.

**Regulatory Status**
There are no medical devices or diagnostic tests related to assisted reproductive techniques that require FDA approval or clearance.
Rationale
This evidence review was created in April 1998 and has been updated regularly with searches of the MEDLINE database. The most recent literature review was conducted through July 3, 2017.

Assessment of efficacy for therapeutic intervention involves a determination of whether the intervention improves health outcomes. The optimal study design for this purpose is a randomized controlled trial (RCT) that includes clinically relevant measures of health outcomes. Intermediate outcome measures, also known as surrogate outcome measures, may also be adequate if there is an established link between the intermediate outcome and true health outcomes. Nonrandomized comparative studies and uncontrolled studies can sometimes provide useful information on health outcomes, but are prone to biases such as noncomparability of treatment groups, placebo effect, and variable natural history of the condition.

The following is a summary of the key literature to date.

Assisted Hatching
Implantation of the embryo in the uterus is a key component of success with in vitro fertilization (IVF). Although the exact steps in implantation are poorly understood, normal rupture of the surrounding zona pellucida with escape of the developing embryo (termed hatching) is crucial. Mechanical disruption of the zona pellucida (ie, assisted hatching) has been proposed as a mechanism to improve implantation rates.

Systematic Reviews
A 2012 Cochrane review and meta-analysis identified 31 randomized controlled trials (RCTs) on assisted hatching (total N=5728 individuals). Twelve studies included women with a poor fertility prognosis, 12 studies included women with a good fertility prognosis, and the remaining 7 studies did not report this factor. Fifteen studies used a laser for assisted hatching, 11 used chemical means, and 5 used mechanical means. Live birth rates were reported in 9 studies (1921 women). A pooled analysis of data from the 9 studies did not find a statistically significant difference between the groups receiving assisted hatching and a control condition (odds ratio [OR], 1.03; 95% confidence interval [CI], 0.85 to 1.26). The rate of live birth was 313 (31%) of 995 in the assisted hatching group and 282 (30%) of 926 in the control group. All 31 trials reported clinical pregnancy rates. In a meta-analysis of all trials, assisted hatching improved the pregnancy rate, but the estimate for the odds ratio was marginally statistically significance (OR=1.13; 95% CI, 1.01 to 1.27).

In 2014, Kissin et al retrospectively reviewed data on assisted hatching in the United States from 2000 to 2010. Data were taken from the Centers for Disease Control and Prevention’s National Assisted Reproductive Technology Surveillance System. The analysis of outcomes was limited to fresh autologous IVF cycles for which a transfer was performed on day 3 or 5. For the total patient population (N=536,852), rates of implantation, clinical pregnancy, and live births were
significantly lower when assisted hatching was used. For example, the live birth rate was 28.3% with assisted hatching and 36.5% without (adjusted odds ratio [AOR], 0.75; 95% CI, 0.70 to 0.81). Moreover, the rate of miscarriage was significantly higher when assisted hatching was used (18.0% vs 13.5%; AOR=1.43; 95% CI, 1.34 to 1.52).

Randomized Controlled Trials
Two additional RCTs comparing laser-assisted hatching with standard of care were published in 2016. Shi et al included 178 patients of advanced maternal age (age range, 35-42 years). There were no statistically significant differences in implantation rates (32.5% in the assisted hatching group vs 39.3% in the control group) or in clinical pregnancy rates (48.8% in the assisted hatching group vs 50.4% in the control group; p-values not reported). Kanyo et al assessed 413 women (mean age, 33 years). In the overall study population, there was no statistically significant difference in the clinical pregnancy rate between the assisted hatching group (33.3%) and the control group (27.4%; p=0.08). However, in the subgroup of patients ages 38 or older, the clinical pregnancy rate was significantly higher in the assisted hatching group (18.4%) than in the control group (11.4%; p=0.03). There was no significant between-group difference in clinical pregnancy rate among women younger than 38 years old. The age groupings (ie, <38 years vs ≥38 years) were not specifically discussed as a prespecified subgroup analysis. Neither trial reported live birth rates.

Section Summary: Assisted Hatching
The available literature has generally not found better outcomes with assisted hatching than with standard of care. A 2012 Cochrane review of heterogenous RCTs found that clinical pregnancy rates but not the live birth rates improved with assisted hatching. In subsequent RCTs, laser-assisted hatching did not improve the clinical pregnancy rate but, in 1 study, there was a higher rate of clinical pregnancy in the subgroup of women 38 years or older. In addition, analysis of a large national database found better outcomes (eg, clinical pregnancy and live birth rates) when assisted hatching was not used.

Embryo Co-Culture
In routine IVF procedures, the embryo is transferred to the uterus on day 2 or 3 of development, when it has between 4 and 8 cells. Embryo co-culture techniques, used successfully in domestic animals, represent an effort to improve the culture media for embryos such that a greater proportion of embryos will reach the blastocyst-stage, in an attempt to improve implantation and pregnancy rates. In addition, if co-culture results in a higher implantation rate, fewer embryos could be transferred at each cycle, resulting in a decreased incidence of multiple pregnancies. A variety of co-culture techniques have been investigated involving the use of feeder cell layers derived from a range of tissues, including the use of human reproductive tissues (ie, oviducts) to nonhuman cells (ie, fetal bovine uterine or oviduct cells) to established cell lines (ie, Vero cells or bovine kidney cells). However, no standardized method of co-culture has emerged, and clinical trials have generally not found that co-culture is associated with an improved implantation or pregnancy rates. For example, Wetzels et al (1998) reported on
an RCT that assigned IVF treatments to co-culture with human fibroblasts or no culture.\textsuperscript{10} Patients in the 2 groups were stratified by age (older or younger than 36 years) and prior IVF attempts (yes vs no). The authors reported that fibroblast co-culture did not affect the implantation or pregnancy rates. In 2015, Ohl et al reported on a novel co-culture technique involving autologous endometrial cell co-culture.\textsuperscript{11} In an interim analysis of 320 patients, the clinical pregnancy rate per embryo transfer was significantly higher in the co-culture group (53.4%) than in the control group (37.3%; \( p=0.025 \)).

\textbf{Section Summary: Embryo Co-Culture}
There is no standardized method of co-culture, and few clinical trials have evaluated outcomes. Most studies have not found improved implantation or pregnancy rates after co-culture. One 2015 RCT reported on a novel co-culture method and an interim analysis of the trial found a higher clinical pregnancy rate with co-culture than with standard practice control group. Additional studies are needed to evaluate this novel co-culture technique. No studies have reported on the impact of co-culture on live birth rates.

\textbf{Cryopreservation of Ovarian Tissue}
Cryopreservation of ovarian tissue or an entire ovary with subsequent auto- or heterotopic transplant has been investigated as a technique to sustain the reproductive function of women or children who are faced with sterilizing procedures, such as chemotherapy, radiotherapy, or surgery, frequently due to malignant diseases. There are a few case reports assessing the return of ovarian function using this technique.\textsuperscript{12,13} There are also case series describing live births using cryopreserved ovarian tissue.\textsuperscript{14-16} However, in general, the technique is not standardized and not sufficiently studied to determine the success rate.\textsuperscript{17,18} In 2011, Johnson and Patrizio commented on whole ovary freezing as a technique of fertility preservation in women with disease or disease treatment that threaten their reproductive tract function.\textsuperscript{19} They concluded: “Although theoretically optimal from the point of view of maximal follicle protection and preservation, the risks and difficulties involved in whole ovary freezing limit this technique to experimental situations.”

\textbf{Section Summary: Cryopreservation of Ovarian Tissue}
This technique has not been standardized, and there are insufficient published data that cryopreservation of ovarian tissue is an effective and safe reproductive technique.

\textbf{Cryopreservation of Oocytes}
Cryopreservation of oocytes has been examined as a fertility preservation option for reproductive-age women undergoing cancer treatment. The mature oocyte is very fragile due to its large size, high water content, and chromosomal arrangement. For example, the mature oocyte is arrested in meiosis, and as such, the chromosomes are aligned in a meiotic spindle. This spindle is easily damaged in freezing and thawing. Survival after thawing may also be associated with sublethal damage, which may further impact on the quality of the subsequent embryo. Moreover, due to the large amount of water, when the oocyte is frozen,
ice crystals can form that can damage the integrity of the cell. To reduce or prevent ice crystals, oocytes are dehydrated using cryoprotectants, which replace the water in the cell. There are 2 primary approaches to cryopreservation: a controlled-rate slow-cooling method and a flash-freezing process known as vitrification. Vitrification, the newer method, is faster and requires a higher concentration of cryoprotectants.

In 2013, the American Society for Reproductive Medicine (ASRM) and Society for Assisted Reproductive Technology (SART) updated their joint guidelines on mature oocyte cryopreservation. A systematic review of the literature, conducted as part of guideline development, identified 4 RCTs comparing outcomes of assisted reproduction with cryopreserved and fresh oocytes. All trials were conducted in Europe and none among patients who desired to preserve fertility after medical treatment (eg, chemotherapy). In these studies, fertilization rates ranged from 71% to 79%, and the clinical pregnancy rates per transfer ranged from 36% to 61%. The largest RCT cited in the guideline (N=600) was published by Cobo et al in Spain in 2010. This trial included oocyte recipients between 18 and 49 years of age who had failed fewer than 3 previous IVF attempts. The primary outcome was the ongoing pregnancy rate; this was defined as the presence of at least 1 viable fetus 10 to 11 weeks after embryo transfer. In an intention-to-treat analysis, the ongoing pregnancy rate was 43.7% in the vitrification group and 41.7% in the fresh oocyte group. Vitrification was considered noninferior to fresh oocyte transfer according to a prespecified margin of difference. The guidelines noted that the available data might not be generalizable to the United States, to clinics with less experience with these techniques, or to other populations (eg, older women, cancer patients). The authors stated that data from the United States are available only from a few clinics and report on young highly selected populations. Pregnancy outcomes and rates of congenital anomalies were not discussed.

Also published in 2013, after the ASRM and SART guidelines was an observational study by Levi Setti et al in Italy. This study compared outcomes in pregnancies achieved with fresh or frozen oocytes. The investigators identified 855 patients in an Italian database who had become pregnant using fresh and/or cryopreserved and thawed oocytes. The authors did not state the reasons for a desire for fertility preservation. The 855 patients had a total of 954 clinical pregnancies; 197 were obtained with frozen oocytes and 757 with fresh oocytes. There were 687 pregnancies from fresh cycle oocytes only, 129 pregnancies with frozen oocytes only, and 138 pregnancies from both fresh and frozen oocyte cycles. The live birth rate was 68% (134/197) from frozen and thawed oocytes and 77% (584/757) fresh oocyte cycles. The live birth rate was significantly higher after fresh cycle oocytes (p=0.008).

Section Summary: Cryopreservation of Oocytes
There are insufficient published data on the safety and efficacy of cryopreservation of oocytes; and data are only available from select clinical settings, generally outside of the United States. Moreover, there is a lack of published data on success rates with cryopreserved oocytes in women who froze oocytes because
they were undergoing chemotherapy. Data on health outcomes (e.g., clinical pregnancy rate, live birth rate) in the population of interest are needed.

**Blastocyst Transfer**

The most common days for embryo transfer in the clinical IVF setting are day 3 or day 5. Embryo transfer at the blastocyst-stage on day 5 continues to be less common than cleavage-stage transfer on day 3. First introduced in clinical practice in 2005, use of blastocyst transfer is increasing in clinical practice. The rationale and reported advantages for blastocyst transfer are: higher implantation and clinical pregnancy rates, a more viable option for limiting to single embryo transfer, more appropriate endometrium-embryo synchronicity, optimization of embryo selection due to embryo development progression, and decreased potential for embryo trauma with biopsy obtained for preimplantation genetic testing. Advances in cell culture techniques and embryology assessments have facilitated the increase in use of blastocyst transfer and research into the technique. Critics of blastocyst transfer have raised concerns about the limitation on the number of available embryos for transfer once the cleavage-stage is passed; critics also cite concern due to uncertainties about the effects of the culture microenvironment, as well as early indicators of a higher rate of adverse pregnancy outcomes.

**Systematic Reviews**

Several systematic reviews of studies comparing outcomes associated with blastocyst-stage transfer with earlier stage transfer have been published. Only the 2012 Cochrane review included RCTs. Cochrane reviewers identified 23 RCTs, 12 of which reported on the rates of live births per couple. A pooled analysis of these trials found a significantly higher live birth rate with blastocyst transfer (292/751 [39%]) than with cleavage-stage transfer (237/759 [31%]). The odds for live birth was 1.40 (95% CI, 1.13 to 1.74). There was no significant difference in the rate of multiple pregnancies between the 2 treatment groups (16 RCTs; OR=0.92; 95% CI, 0.71 to 1.19). In addition, there was no significant difference in the miscarriage rate (14 RCTs; OR=1.14; 95% CI, 0.84 to 1.55).

In 2016, an update to the 2012 Cochrane review placed further focus on whether blastocyst-stage (day 5-6) embryo transfers improved the live birth rates, and other associated outcomes, compared with cleavage-stage (day 2-3) embryo transfers. Data from four new studies, three of which were published papers and resulted in a total of 27 parallel-design RCTs that included 4031 couples or women. The data from a fourth study was only available in abstract form and reported on outcomes from a multicenter trial comparing blastocyst with day 2-3 transfer in intracytoplasmic sperm injection (ICSI) cycles for male factor infertility. There were no exclusions from the 2012 review. The live birth rate following fresh transfer was higher in the blastocyst transfer group (OR=1.48; 95% CI, 1.20 to 1.82; 13 RCTs, 1630 women, \( I^2 = 45\% \), low-quality evidence). There was no evidence of a difference between groups in rates of cumulative pregnancy per couple following fresh and frozen-thawed transfer after 1 oocyte retrieval (OR=0.89; 95% CI, 0.64 to 1.22; 5 RCTs, 632 women, \( I^2 = 71\% \), very low quality evidence). The clinical pregnancy rate was also higher in the blastocyst transfer
group, following fresh transfer (OR=1.30; 95% CI, 1.14 to 1.47; 27 RCTs, 4031 women, \(I^2=56\%\), moderate-quality evidence). Embryo freezing rates were lower in the blastocyst transfer group (OR=0.48; 95% CI, 0.40 to 0.57; 14 RCTs, 2292 women, \(I^2=84\%\), low-quality evidence). Failure to transfer any embryos was higher in the blastocyst transfer group (OR=2.50; 95% CI, 1.76 to 3.55; 17 RCTs, 2577 women, \(I^2=36\%\), moderate-quality evidence).

The data for rates of multiple pregnancy and miscarriage were incomplete in 70% of the trials and limit conclusions concerning the following findings. There was no evidence of a difference between the groups in rates of multiple pregnancy (OR=1.05, 95% CI, 0.83 to 1.33; 19 RCTs, 3019 women, \(I^2=30\%\), low-quality evidence) or miscarriage (OR=1.15, 95% CI, 0.88 to 1.50; 18 RCTs, 2917 women, \(I^2=0\%\), low-quality evidence).

A 2013 systematic review identified 8 observational studies analyzing singleton births following embryo transfer at the blastocyst or cleavage stage and reporting obstetric and/or perinatal outcomes. Meta-analysis of 6 studies found a significantly higher rate of preterm delivery less than 37 weeks after blastocyst-stage transfer compared with cleavage-stage transfer (relative risk [RR], 1.27; 95% CI, 1.22 to 1.31); the absolute increase in risk was 2% (95% CI, 1% to 4%). Other pooled analyses of 2 to 3 studies each did not find significantly increased rates of low birth weight less than 1500 grams, congenital anomalies, or perinatal mortality following blastocyst-stage vs cleavage-stage embryo transfer.

**Observational Studies**

A 2010 retrospective cohort study reported on risks associated with blastocyst transfer. Data were taken from the Swedish Medical Birth Register. There were 1311 infants born after blastocyst transfer and 12,562 born after cleavage-stage transfer. There were no significant differences in the rates of multiple births (10% after blastocyst transfer vs 8.9% after cleavage-stage transfer). Among singleton births, the rate of preterm birth (<32 weeks) was 18 (1.7%) of 1071 in the blastocyst-transfer group and 142 (1.35%) of 10,513 in the cleavage-stage transfer group. In a multivariate analysis controlling for year of birth, maternal age, parity, smoking habits, and body mass index, the AOR was 1.44 (95% CI, 0.87 to 2.40). The rate of low birth weight singletons (<1500 g or <2500 g) did not differ significantly between the blastocyst-transfer group and the cleavage-stage transfer group. There was a significantly higher rate of relatively severe congenital malformation (eg, spina bifida, cardiovascular defects, cleft palate) after blastocyst transfer (61/1311 [4.7%]) than after cleavage-stage transfer (509/12,562 [4.1%]; AOR=1.33; 95% CI, 1.01 to 1.75). The groups did not differ significantly in their rates of low APGAR scores, intracranial hemorrhage rates, respiratory diagnoses, or cardiovascular malformations. Respiratory diagnoses were given to 94 (7.2%) of 1311 infants born after blastocyst transfer and to 774 (6.2%) of 12,562 after cleavage-stage transfer (OR=1.15; 95% CI, 0.90 to 1.47). The study was not randomized and, although the investigators adjusted for some potential confounders (eg, age, parity), there might have been other differences between groups that affected outcomes.
In 2016, Ginström Ernstad et al published another retrospective registry cohort study using data crosslinked between the Swedish Medical Birth Register, the Register of Birth Defects, and the National Patient Register. All singleton deliveries after blastocyst transfer in Sweden from 2002 through 2013 were compared with deliveries after cleavage-stage transfer and deliveries after spontaneous conception. There were 4819 singletons born after blastocyst transfer, 25,747 after cleavage-stage transfer, and 1,196,394 after spontaneous conception. Singletons born after blastocyst transfer had no increased risk of birth defects compared with singletons born after cleavage-stage transfer (AOR=0.94; 95% CI, 0.79 to 1.13) or spontaneous conception (AOR=1.09; 95% CI, 0.92 to 1.28). Perinatal mortality was higher in the blastocyst group vs the cleavage-stage group (AOR=1.61; 95% CI, 1.14 to 2.29). When comparing singletons born after blastocyst transfer to singletons born after spontaneous conception, a higher risk of preterm birth (<37 weeks) was seen (AOR=1.17; 95% CI, 1.05 to 1.31). Singletons born after blastocyst transfer had a lower rate of low birthweight (AOR=0.83; 95% CI, 0.71 to 0.97) than singletons born after cleavage-stage transfer. The rate of being small for gestational age was also lower in singletons born after blastocyst transfer than after both cleavage-stage conception (AOR=0.71; 95% CI, 0.56 to 0.88) and spontaneous conception (AOR=0.70; 95% CI, 0.57 to 0.87). The risks of placenta previa and placental abruption were higher in pregnancies after blastocyst transfer than in pregnancies after cleavage-stage (AOR=2.08; 95% CI, 1.70 to 2.55 and AOR=1.62; 95% CI, 1.15 to 2.29, respectively) and after spontaneous conception (AOR=6.38; 95% CI, 5.31 to 7.66 and AOR=2.31; 95% CI, 1.70 to 3.13, respectively).

**Section Summary: Blastocyst Transfer**

An updated 2016 Cochrane review of 27 RCTs compared the effectiveness of blastocyst transfers with cleavage-stage transfers. The primary outcomes of live birth and cumulative clinical pregnancy rates were higher with fresh blastocyst transfer. There were no differences between groups in multiple pregnancies or early pregnancy loss (miscarriage). The main limitation of the RCTs was serious risk of bias, associated with failure to describe acceptable methods of randomization and unclear or high risk of attrition bias. Differences in outcomes with the use of cryopreserved blastocysts and use of cleavage-stage embryos have been reported, and the mechanisms are not well-understood. There are conflicting reports from retrospective studies on the incidence of pregnancy and neonatal adverse outcomes, including low birth weight and increased congenital anomalies.

**Intracytoplasmic Sperm Injection for Male Factor Infertility**

ICSI is performed in cases of male factor infertility when either insufficient numbers of sperm, abnormal morphology, or poor motility preclude unassisted IVF. Fertilization rates represent an intermediate outcome; the final outcome is the number of pregnancies per initiated cycle or per embryo transfer. This outcome was reported in relatively large series published in the mid-1990s as between 45% and 50%. At the time, those rates were very competitive with those of the standard IVF.
More recently, in 2015, Boulet et al published a large retrospective analysis of the outcomes following ICSI vs standard IVF (data captured from the Centers for Disease Control and Prevention’s National Assisted Reproductive Technology Surveillance System from 2008 to 2012). During that time, there were data on 494,907 fresh IVF cycles. A total of 74.6% of cycles used ICSI, with 92.9% of the cycles involving male factor infertility and 64.5% of the cycles not involving male factor infertility. Among couples with male factor infertility, there was a statistically significantly lower rate of implantation after ICSI (25.5%) than after standard IVF (25.6%; p=0.02); however, the degree of difference between groups may not be clinically significant. Rates of clinical intrauterine pregnancy and live birth did not differ significantly between ICSI and standard IVF. In couples without male factor infertility, implantation, clinical pregnancy, and live birth rates were all significantly higher with standard IVF than with ICSI.

Adverse Events

A 2015 systematic review and meta-analysis by Massaro et al examined adverse events for ICSI and standard IVF without ICSI. Twenty-two observational studies were included; no RCTs were identified. Meta-analysis of 12 studies found a significantly increased odds of congenital genitourinary malformations in children conceived using ICSI vs standard IVF (pooled OR=1.27; 95% CI, 1.02 to 1.58; p=0.04; \(I^2=0\)). Five studies in this analysis were considered at high risk of bias, and a pooled analysis of the 4 studies considered at low risk of bias did not find ICSI associated with a statistically increased odds of genitourinary malformations.

Section Summary: Intracytoplasmic Sperm Injection for Male Factor Infertility

There is a lack of RCTs comparing ICSI with standard IVF. Observational studies have found similar rates of clinical pregnancy and live births after ICSI and standard IVF, but those observational studies are subject to limitations (eg, selection bias). A 2015 meta-analysis of observational studies found a significantly higher rate of congenital genitourinary malformations in children born after ICSI vs IVF, but there was no significant difference when only studies with low risk of bias were included in the analysis. RCTs comparing health outcomes after ICSI for male factor infertility with standard IVF would strengthen the evidence base.

Cryopreservation of Testicular Tissue in Adult Men With Azoospermia

Testicular sperm extraction refers to the collection of sperm from testicular tissue in men with azoospermia. Extraction of testicular sperm may be performed at the time of a diagnostic biopsy or as a subsequent procedure, specifically for the collection of spermatozoa. Spermatozoa may be isolated immediately and a portion used for an ICSI procedure at the time of oocyte retrieval from the partner, with the remainder cryopreserved. Alternatively, the entire tissue sample can be cryopreserved with portion thawed and sperm isolation performed at subsequent ICSI cycles. This technique appears to be a well-established component of the overall ICSI procedure; cryopreservation of either the isolated sperm or the tissue sample eliminates the need for multiple biopsies to obtain fresh tissue in the event of a failed initial ICSI cycle. However, clinical trials
evaluating health outcomes after cryopreservation of testicular tissue in adult men with azoospermia were not identified.

**Section Summary: Cryopreservation of Testicular Tissue in Adult Men With Azoospermia**
While cryopreservation of testicular tissue in adult men with azoospermia is a well-established component of the ICSI procedure, there is a lack of clinical trials to support this treatment.

**Cryopreservation of Testicular Tissue in Prepubertal Boys Undergoing Cancer Therapy**
A potential application of cryopreservation of testicular tissue is its potential to preserve the reproductive capacity in prepubertal boys undergoing cancer chemotherapy; the typical cryopreservation of an ejaculate is not an option in these patients. It is hypothesized that reimplantation of the frozen-thawed testicular stem cells will reinitiate spermatogenesis or, alternatively, spermatogenesis could be attempted in vitro, using frozen-thaw spermatogonia. While these strategies have been explored in animals, there are inadequate human studies. 39,40

**Section Summary: Cryopreservation of Testicular Tissue in Prepubertal Boys Undergoing Cancer Therapy**
No clinical trials were identified evaluating the safety and efficacy of cryopreservation of testicular tissue in prepubertal boys undergoing cancer therapy.

**Potential Adverse Effects to Offspring Associated With Assisted Reproductive Techniques**
A number of systematic reviews and registry studies have evaluated potential adverse effects in offspring after assisted reproduction. Several reviews have addressed risk of birth defects.41-43 The review with the most data was published by Hansen et al (2013). 42 They examined 45 cohort studies with outcomes in 92,671 infants born following assisted reproduction and 3,870,760 naturally conceived infants. In a pooled analysis of the data, there was a higher risk of birth defects in infants born using reproductive techniques (RR=1.32; 95% CI, 1.24 to 1.42). The risk of birth defects was also elevated when the analysis was limited to the 6 studies conducted in the United States or Canada (RR=1.38; 95% CI, 1.16 to 1.64). Another review, published by Davies et al (2012), included data on 308,974 live births in Australia, 6163 of which followed use of ART. 43 There was a higher rate of birth defects after assisted conception (8.3%) compared with births to fertile women who did not need assisted reproduction (5.8%; unadjusted OR=1.47; 95% CI, 1.33 to 1.62). The risk of birth defects was still significantly elevated but was lower in an analysis that adjusted for other factors that might increase risk (eg, maternal age, parity, maternal ethnicity, maternal smoking during pregnancy, socioeconomic status; OR=1.28; 95% CI, 1.16 to 1.41).

A 2015 systematic review by Kettner et al considered potential adverse events in children of various ages. 44 Reviewers included controlled studies reporting at least
1 postnatal morbidity outcome in children who were and were not conceived using assisted reproductive. Twenty studies met the eligibility criteria; 30 were cohort studies, and 8 were case-control studies. There were no strong, consistent associations between use of reproductive techniques and childhood disease. For example, no statistically significant differences were found in rates of the following in children conceived spontaneously or with ART: chronic diseases (2 studies), cancer (3 studies), and allergic disease (5 studies). Findings were mixed on the risk of infectious and parasitic diseases. In the 8 studies examining this outcome, odds ratios varied between 0.37 and 5.7, and most results were not statistically significant. Rates of asthma or obstructive bronchitis were examined in 8 studies; three found significantly increased risk in children conceived by ART vs conceived spontaneously.

A Danish registry study published in 2013 addressed the risk of childhood and adolescent mental disorders following assisted reproduction.45 The study included 524 children born after IVF or ICSI and 22,009 children born after spontaneous conception. In an analysis adjusted for potential confounders, compared with spontaneously conceived children, there were no statistically significant increases in mental retardation, disorders of psychological development (eg, autism spectrum disorders, speech and language disorders, others), attention-deficit/hyperactivity disorder or conduct, emotional, or social disorders.

Summary of Evidence
For individuals who have infertility who receive IVF with assisted hatching, the evidence includes RCTs, a systematic review, and a large observational study. Relevant outcomes are health status measures and treatment-related morbidity. RCTs have not shown that assisted hatching improves the live birth rate compared with standard care. Findings on clinical pregnancy rates after assisted hatching were mixed, but RCTs generally did not find improvements with assisted hatching vs standard care. A large observational study found that assisted hatching was associated with worse outcomes. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have infertility who receive IVF with embryo co-culture, the evidence includes RCTs and case series. Relevant outcomes are health status measures and treatment-related morbidity. Most clinical trials have not found improved implantation or pregnancy rates after co-culture, and studies have not reported live birth rates. Moreover, co-culture techniques have not been standardized. One RCT did report a higher clinical pregnancy rate with co-culture than with a standard practice control group—however, this process used a novel technique that has not yet been fully evaluated. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have cancer who will undergo treatment that may lead to infertility who receive cryopreservation of ovarian tissue, the evidence includes case series that have reported technique as well as pregnancies and live births after transplantation. Relevant outcomes are health status measures and treatment-related morbidity. The technique has not been standardized, and there
is a lack of controlled studies on health outcomes following cryopreservation of ovarian tissue. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have cancer who will undergo treatment that may lead to infertility who receive cryopreservation of oocytes, the evidence includes RCTs and a systematic review on the technique in related populations. Relevant outcomes are health status measures and treatment-related morbidity. The systematic review found that fertilization rates ranged from 71% to 79%, and the clinical pregnancy rates per transfer ranged from 36% to 61%. The available studies have been conducted in highly selected populations and may not be generalizable to the population of interest, women with cancer. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have infertility who receive IVF with blastocyst transfer, the evidence includes RCTs and meta-analyses. Relevant outcomes are health status measures and treatment-related morbidity. RCTs and meta-analyses have found that blastocyst transfer is associated with higher live birth rates than cleavage-stage transfer. One retrospective cohort study has reported a significantly higher rate of preterm birth after blastocyst-stage vs cleavage-stage transfer—but did not find increased risks of other outcomes such as low birth rate or perinatal mortality. A retrospective registry review of a similar population reported different findings. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have male factor infertility who receive IVF with ICSI, the evidence includes observational studies and a systematic review. Relevant outcomes are health status measures and treatment-related morbidity. No RCTs are available. Observational studies, which are subject to design limitations (eg, selection bias), have found similar rates of clinical pregnancy and live birth after ICSI and standard IVF, and a meta-analysis of observational studies found a higher rate of genitourinary malformations in children born after ICSI (but only when lower quality studies were included in the analysis). Multiple RCTs are needed to compare health outcomes after ICSI for male factor infertility and standard IVF. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have azoospermia who receive cryopreservation of testicular tissue as part of ICSI, the evidence includes no clinical trials. Relevant outcomes are health status measures and treatment-related morbidity. Cryopreservation of testicular tissue in adult men with azoospermia is a well-established component of the ICSI procedure. However, there is a lack of clinical trials. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who are prepubertal boys with cancer who receive cryopreservation of testicular tissue, the evidence includes no clinical trials. Relevant outcomes are health status measures and treatment-related morbidity. No clinical trials were identified evaluating the safety and efficacy of cryopreservation of testicular tissue.
in prepubertal boys undergoing cancer therapy. The evidence is insufficient to determine the effects of the technology on health outcomes.

**Supplemental Information**

**Clinical Input From Physician Specialty Societies and Academic Medical Centers**

While the various physician specialty societies and academic medical centers may collaborate with and make recommendations during this process, through the provision of appropriate reviewers, input received does not represent an endorsement or position statement by the physician specialty societies or academic medical centers, unless otherwise noted.

In response to requests, input was received from 4 physician specialty societies and 2 academic medical centers while this policy was under review in 2012. There was general agreement that intracytoplasmic sperm injection and cryopreservation of testicular tissue in adult men with azoospermia as part of an intracytoplasmic sperm injection procedure may be considered medically necessary. Three of 5 reviewers who responded agreed that co-culture of embryos is considered investigational. In addition, 4 of 5 reviewers did not agree that blastocyst transfer is investigational; these reviewers considered blastocyst transfer to be medically necessary to decrease multiple gestations. Three of 6 reviewers agreed that cryopreservation of ovarian tissue or oocytes is investigational. The other three thought that cryopreservation of oocytes, but not ovarian tissue, is medically necessary. Clinical input on other policy statements was more variable.

**Practice Guidelines and Position Statements**

**American Society for Reproductive Medicine and Society for Assisted Reproductive Technology**

In 2014, the American Society for Reproductive Medicine (ASRM) and the Society for Assisted Reproductive Technology (SART) published joint guidelines on assisted hatching in in vitro fertilization (IVF). The single recommendation in these guidelines stated that assisted hatching should not be used routinely for all patients undergoing IVF.

In 2013, ASRM and SART published joint guidelines on mature oocyte cryopreservation. The guidelines stated: “evidence indicates that oocyte vitrification and warming should no longer be considered experimental” and included the following recommendations:

- “In patients facing infertility due to chemotherapy or other gonadotoxic therapies, oocyte cryopreservation is recommended with appropriate counseling.”
- “More widespread clinic-specific data on the safety and efficacy of oocyte cryopreservation in donor populations are needed before universal donor oocyte banking can be recommended.”
“There are not yet sufficient data to recommend oocyte cryopreservation for the sole purpose of circumventing reproductive aging in healthy women.”
“More data are needed before this technology should be used routinely in lieu of embryo cryopreservation.”

A 2012 committee opinion from ASRM and SART stated that intracytoplasmic sperm injection (ICSI) is a safe and effective treatment for male factor infertility.\textsuperscript{47} The opinion also indicated that ICSI for unexplained fertility, low oocyte yield, and advanced maternal age does not improve clinical outcomes. The opinion included a statement that ICSI may benefit patients undergoing IVF with preimplantation genetic testing, in vitro matured oocytes, and cryopreserved oocytes.

ASRM and SART also issued a committee opinion on blastocyst transfer in 2008,\textsuperscript{48} which was updated in 2013. The opinion concluded that “evidence supports blastocyst transfer in ‘good prognosis’ patients.”

**American College of Obstetricians and Gynecologists**
In 2014, The American College of Obstetricians and Gynecologists endorsed the 2013 ASRM-SART joint guidelines on mature oocyte cryopreservation.\textsuperscript{49} The endorsement was affirmed in 2016.

**American Society of Clinical Oncology**
In 2013, the American Society of Clinical Oncology published guidelines on fertility preservation for patients with cancer.\textsuperscript{50} The guidelines included the following recommendations for males and females, respectively.

“Recommendation 2.1. Sperm cryopreservation: Sperm cryopreservation is effective, and health care providers should discuss sperm banking with postpubertal males receiving cancer treatment.

Recommendation 2.2. Hormonal gonadoprotection: Hormonal therapy in men is not successful in preserving fertility. It is not recommended.

Recommendation 2.3. Other methods to preserve male fertility: Other methods, such as testicular tissue cryopreservation and reimplantation or grafting of human testicular tissue, should be performed only as part of clinical trials or approved experimental protocols....”

“Recommendation 3.1. Embryo cryopreservation: Embryo cryopreservation is an established fertility preservation method, and it has routinely been used for storing surplus embryos after in vitro fertilization.

Recommendation 3.2. Cryopreservation of unfertilized oocytes: Cryopreservation of unfertilized oocytes is an option, particularly for patients who do not have a male partner, do not wish to use donor sperm, or have religious or ethical objections to embryo freezing....”
Agency for Healthcare Research and Quality
In 2008, the Agency for Healthcare Research and Quality published an evidence report on the effectiveness of assisted reproductive technology. The report reviewed evidence on the outcomes of interventions used in ovulation induction, superovulation, and IVF for the treatment of infertility. Reviewers concluded that interventions for which there was sufficient evidence to demonstrate improved pregnancy or live birth rates included: (a) administration of clomiphene citrate in women with polycystic ovarian syndrome; (b) metformin plus clomiphene in women who fail to respond to clomiphene alone; (c) ultrasound-guided embryo transfer, and transfer on day 5 postfertilization, in couples with a good prognosis; and (d) assisted hatching in couples with previous IVF failure. There was insufficient evidence on other interventions. Infertility itself is associated with most of the adverse longer term outcomes. Reviewers concluded that despite the large emotional and economic burden resulting from infertility, there was relatively little high-quality evidence to support the choice of specific interventions. The Agency’s conclusion was based primarily on studies that had pregnancy rates as the primary end point, not live births. In addition, studies used multiple assisted hatching techniques.

U.S. Preventive Services Task Force Recommendations
Not applicable.

Medicare National Coverage
There is no national coverage determination. In the absence of a national coverage determination, coverage decisions are left to the discretion of local Medicare carriers.

Ongoing and Unpublished Clinical Trials
Some currently unpublished trials that might influence this review are listed in Table 1.

**Billing Coding/Physician Documentation Information**
(See Tables Above)

The following CPT codes describe procedures that would be routinely performed in all ART procedures involving in vitro fertilization (IVF):

- **58970**: Oocyte retrieval
  - Either:
    - **89250**: Culture and fertilization of oocyte, less than 4 days; **OR**
    - **89272**: Culture and fertilization of oocyte, greater than 4 days.
  - Either
    - **89268**: Insemination of oocytes; **OR**
    - **89280 / 89281**: Assisted oocyte fertilization, microtechnique, less than or greater than 10 oocytes, respectively
    - **89260** or **89261**: Sperm isolation, simple or complex
    - **89255**: Preparation of embryo for transfer
    - **58974** or **58976**: Embryo, zygote, or gamete transfer, intrauterine or intrafallopian

The following CPT codes describe procedures that would not be routinely performed in all ART procedures involving IVF.

- **89257**: Sperm identification from aspiration. Only performed in patients with oligospermia who have undergone a prior testicular or epididymal aspiration; typically performed as a part of an intracytoplasmic sperm injection procedure (ICSI).
- **89264**: Sperm identification from biopsied testis tissue. Only performed in patients with oligospermia who have undergone a prior testicular biopsy; typically performed as a part of an ICSI procedure.
- **89253**: Assisted hatching. Only performed in women over the age of 40, or in cases in which prior ART attempts resulted in failed implantation.
- **89256**: Preparation of cryopreserved embryos
- **89258**: Cryopreservation of embryos
- **89259**: Cryopreservation of sperm
- **89342-89356**: Code range, cryopreservation and thawing of various components

The following CPT codes describe procedures that would be routinely performed as part of an intrauterine or intracervical artificial insemination:

- **58321**: Artificial insemination; intracervical
- **58322**: Artificial insemination; intrauterine
- **58323**: Sperm washing for artificial insemination
Note also that other “S” codes are available (see Coding section, above) that describes in vitro fertilization globally.

- **S4013**: Complete cycle, gamete intrafallopian transfer (GIFT), case rate
- **S4014**: Complete cycle, zygote intrafallopian transfer (ZIFT), case rate
- **S4017**: Incomplete cycle, treatment cancelled prior to stimulation, case rate
- **S4018**: Frozen embryo transfer procedure cancelled before transfer, case rate
- **S4042**: Management of ovulation induction (interpretation of diagnostic tests and studies, non-face-to-face medical management of the patient), per cycle

**ICD-10 Codes.**

- **N46.01-** Male infertility, code range
- **N46.9**
- **N73.6** Female pelvic peritoneal adhesions
- **N80.1-** Endometriosis code range
- **N80.9**
- **N97.1-** Female infertility, code range
- **N97.9**
- **N99.4** Postprocedural pelvic peritoneal adhesions

**Additional Policy Key Words**

N/A

**Policy Implementation/Update Information**

- **10/1/88** New policy.
- **12/1/01** Added new codes, no policy statement changes.
- **12/1/02** No policy statement changes.
- **12/1/03** No policy statement changes.
- **12/1/04** Added S-codes, no policy statement changes.
- **12/1/05** Formatting changes, no policy statement changes.
- **12/1/06** Policy statement revised indicate cryopreservation of testicular tissue in prepubertal boys is investigational (89335).
- **12/1/07** No policy statement changes.
- **12/1/08** No policy statement changes.
- **12/1/09** No policy statement changes. Codes 0058T and 0059T were deleted effective 1/1/2009.
- **12/1/10** No policy statement changes.
- **12/1/11** No policy statement changes.
- **12/1/12** Policy statement changed to include blastocyst transfer as medically necessary.
- **12/1/13** No policy statement changes.
- **12/1/14** No policy statement changes.
- **12/1/15** Intracytoplasmic sperm injection in the absence of male factor infertility added to investigational statement.
- **12/1/16** No policy statement changes.
- **12/1/17** No policy statement changes.
